1 Greedy approach

We model the set of cards as an array of integers of size N. We do not consider a more realistic model (N even, at most 52 cards, values between 2 and 14, at most 4 cards of each value) because we focus (except for this section) on exact algorithms which ignore these details.
An implementation of the simulation of a game, where both players employ the same greedy strategy is the following:

Algorithm 1 Simulate greedy

```
S ← create_random_array(N);
first ← 0;
last ← N − 1;
wait_for_the_opponent();
N ← length(S) − 1;
while N > 0 do
    if S[first] > S[last] then
        first ← first + 1;
    else
        last ← last − 1;
    end if
    N ← N − 1;
    if N > 0 then
        wait_for_the_opponent();
        N ← N − 1;
    end if
end while
```

In the code above, $wait\_for\_the\_opponent()$ lets the opponent make their move (if it's the first one, the opponent has an option not to do it). This procedure also updates $fisrt$ or $last$. **This procedure is assumed to be deterministic**: for example, if the first and the last card have the same value, the opponent always chooses the left one.

Using greedy strategy against an opponent playing a greedy strategy is **not optimal**: in the following game the opponent can be defeated, but not with the greedy strategy (whoever is taking the first card):

$$\{3\ 10\ 3\ 9\ 5\ 2\}$$

If the player takes the first card he can go: $right - right - left$ (or $2 - 9 - 10$). Otherwise, if the opponent takes 3, he can go $left - left - left$ (or $10 - 9 - 2$). In both cases this wins the game, while applying greedy strategy doesn't.

Using a greedy algorithm with another metric was taken into consideration. The suggested metric was maximizing the immediate score resulting by making a

choice: $max(value(plyer's\ choice)-value(opponent's\ choice\ given\ player's\ choice))$. Howerver, the simulations showed that it resulted in a lower win ratio: about 0.15 versus 0.45 using standard greedy strategy.

2 Optimal solution by exhaustion

We assume that after a dog's choice we have two possible solutions for the player's choice.

- In case the dog goes first, we have:
  optimal_solution opt = Dogs_turn(0, N-1)
- In case the dog chooses to go second, we have:
  optimal_solution opt = best_score(explore_solution(0, N-1, left),
  explore_solution(0, N-1, right))

Time complexity is exponential: $T(N) = 2^{(N/2)}$
Where the space complexity is linear: $S(N) = O(N)$ The amount of information store is at most K where K is the height of the recursive call function.

---

optimal_solution : {
  string *path*; ▷ stores the indexes of the cards
  int *score*; ▷ best total score that we can have reaching this sub-problem from the root
}

Algorithm 2 Complete space exploration

```
procedure DOGS_TURN(i, j)        ▷ i, j : the indexes of the rightmost and leftmost cards
    if i ≤ j then
        optimal_solution opt;
        if S[i] ≥ S[j] then
            value ← S[j];
            j − −;
            index ← j;
        else
            value ← S[i];
            i + +;
            index ← i;
        end if
        right_opt ← explore_solution(i, j, right);
        left_opt ← explore_solution(i, j, left);
        if left_opt.score ≥ right_opt.score then
            opt.path ← append(left_opt.path, index);
            opt.score ← left_opt.score + value;
        else
            opt.path ← append(right_opt.path, index);
            opt.score ← right_opt.score + value;
        end if
        return opt;
    else
        return NULL;
    end if
end procedure
```

Algorithm 3

```
procedure explore_solution(i, j, choice)   ▷ i, j : indexes of the rightmost and leftmost cards, choice: which card to choose
    if i ≤ j then
        optimal_solution opt;
        if choice = right then
            value ← S[j];
            j − −;
            index ← j;
        else
            value ← S[i];
            i + +;
            index ← i;
        end if
      current_opt ← Dogs_turn(i, j);
        opt.path ← append(current_opt.path, index);
        opt.score ← value + current_opt.score
        return opt;
    else
        return NULL;
    end if
end procedure
```

3 Dynamic approach

We use the cache 2 dimensions array of size n by n where n is the total number of cards that we played. We have $C[n]$ is array store the card in order and $cache[n][n]$ is the array of cache.

The data structure for an element in cache[i][j]

Algorithm 4 Data structure of cache element

```
int score                ▷ Store the best score to arrive to that elements
string path   ▷ String to store the path to reach that elements with best score
```

Algorithm 5

```
procedure cache_compute(l, r)
    for k from 0 to N do                          ▷ Diagonal has N elements
        dog_take_card(l, r)    ▷ Choose the higher card between C[l] and C[r]
        j = 0
        for i from 0 to k do
            if k − i == 0 then
                cache[0][j].score = C[r++]
                cache[0][j].path = 'R'
                r = r -1
            else if j == 0 then
                cache[k − i][0].score = C[l++]
                cache[k − i][0].path = 'L'
                l = l + 1
            else
                if cache[k − i − 1][j].score ≤ cache[k − i][j − 1].score then
                    cache[k − i][j].score = cache[k − i][j − 1].score + C[r++]
                    cache[k − i][j].path = append(cache[k − i][j − 1].path, 'R')
                    r = r -1
                else
                    cache[k − i][j].score = cache[k − i − 1][j].score + C[l++]
                    cache[k − i][j].path = append(cache[k − i − 1][j].path, 'L')
                    l = l + 1
                end if
            end if
            j = j + 1
        end for
    end for
end procedure
```

Since we only have N moves, the square matrix (2 dimension array) is only used for half of it (the upper left triangle) By travesing the cache diagonal, we can find the solution with the max value.

Algorithm 6

```
procedure travesing_cache_diagonal
    max = 0
    for i = 0; i < N; i++ do
        x = 0
        y = N
        if max ≤ cache[x][y] then
            max = cache[x][y]
        end if
        x = x + 1
        y = y − 1
    end for
     return max
end procedure
```

4 Space and Time Complexity of Dynamic Approach

4.1 Space complexity

In this dynamic approach we use a cache of 2 dimensions array. The array has the size of N by N then the space for storing this cache is N^2

In addition, we need to store the card order in another array of 1 dimension with size N.

Our space complexity is O(N^2)

4.2 Time Complexity

We need compute the cache which cost $N^2/2$

We have to travesing the cache which cost N times.

So that computation has the complexity of O($N^2/2$).

5 Conclusion

In this APP, we studied the dynamic approach for a card play problem.

By using the cache concept. We stored the same problem computation in a 2 dimensions array. so we reduced the amount of computation for the same problem.
